Received August 31, 2005

Facile alkan functionalization by means of the insertion of :CHCO2Et from ethyl diazoacetate, into carbon–hydrogen bonds mediated by catalytic amounts of (NHC)MCl (NHC = N-heterocyclic ligand: M = Cu, Au) and a halide scavenger MX has been achieved. This chemistry includes the insertion of the carbene fragment into alkane primary positions with Cu- and Au-based catalysts. The nature of the counterion X and of the NHC ligand has a significant effect on the overall yields and regioselectivity of the reaction.

Introduction

The metal-catalyzed transfer of a carbene unit, :CR1R2, from diazo compounds N2CR1R2 has been extensively studied during the last few decades.1 The main transformations involving this fragment have centered on its addition to unsaturated bonds or, alternatively, its insertion into saturated X–H bonds. The most interesting example is when X is carbon, a case that results in the functionalization of carbon–hydrogen bonds by carbene insertion.2 This procedure (Scheme 1) has been extensively employed in intramolecular reactions; however the intermolecular counterpart has been described only with a few metal-based catalysts.3 The seminal work by Noels and co-workers4 with rhodium acetate was followed by work from several other groups5 that aimed at developing new catalysts based on rhodium. This methodology was quite limited in scope, and it was not until the end of the past decade when work by Davies and co-workers6 led to the renaissance of this method for the functionalization of carbon–hydrogen bonds. Interestingly systems based on copper7a–d and silver8a–f have also been reported to insert a :CHCO2Et unit from ethyl diazoacetate into C–H bonds of several saturated substrates.

We have very recently reported on the catalytic properties of the complex (IPr)CuCl (1) [IPr: 1,3-bis(diisopropylphenyl)imidazol-2-ylidene] (Scheme 2) in the transfer of the :CHCO2Et unit from ethyl diazoacetate to olefins, amines, and alcohols.8 We have also prepared and characterized the gold analogue (IPr)AuCl (2) and reported its catalytic competency for carbene transfer reactions, in what to the best of our knowledge represents the first example of this metal mediating hydrogen bonds mediated by catalytic amounts of (NHC)MCl (NHC = N-heterocyclic ligand: M = Cu, Au) and a halide scavenger MX has been achieved. This chemistry includes the insertion of the carbene fragment into alkane primary positions with Cu- and Au-based catalysts. The nature of the counterion X and of the NHC ligand has a significant effect on the overall yields and regioselectivity of the reaction.

such a transformation.\(^9\) With this recent finding, all metals in groups 8–11 have now been reported to decompose a diazo compound with the subsequent transfer of a carbene unit.\(^{10}\) Despite these interesting catalytic performances, the selective activation of primary C–H bonds by this method still remains a challenge, with the notable exceptions in reactions mediated by rhodium\(^4\) and silver.\(^{7\text{d,e}}\) With this specific selectivity in mind, we decided to investigate the potential of complexes 1 and 2 as precatalysts for the insertion of EDA into the carbon–hydrogen bonds of alkanes.

**Results and Discussion**

Initial catalytic tests were carried out using cyclohexane, as the model substrate, in the presence of 1 or 2. Not surprisingly, no EDA was consumed under these conditions, even after a few hours. This is in agreement with the previously reported behavior of 1. In the present (NHC)MCl precatalyst systems, we have proposed\(^8\) a cationic active species bearing a chloride counterion. The formation of an ionic, catalytically active species in situ proved feasible in the presence of donor substrates (olefins, amines, alcohols). However, the low donor ability of cyclohexane precluded, in the present case, the formation of the catalytic species. Therefore, the active catalytic species was generated by using an equimolar mixture of 1 or 2 and the sodium salt of the well-known noncoordinating anion tetrakis-(3,5-bis(trifluoromethyl)phenyl)borate, BAr\(^{′}\) (Scheme 2).\(^{11}\) The use of this additive rendered the transformation effective with high yields (based on EDA: 80% for 1 and 84% for 2). NMR studies of the crude products carried out after reaction completion showed resonances identical to those observed when 1 or 2 was reacted with NaBAr\(^{′}\) in the absence of EDA and/or alkane. This experiment suggests that catalyst death or deactivation does not occur readily in the present system.

Having demonstrated the capabilities of this system to promote the insertion of the carbene :CHCO\(_2\)Et group into the C–H bond of cyclohexane, we then performed a study with a family of precatalyst formed varying the metal, the halide counterion, and the NHC ligand (Scheme 3), to observe their independent effect on the catalytic reaction. To explore such effects, we chose 2,3-dimethylbutane as the substrate, where both tertiary and primary C–H bonds are available.

**Effect of the Metal: Cu versus Au**

In good accord with the previous observations with cyclohexane, no reaction of 2,3-dimethylbutane and EDA was observed in the presence of 1 and 2. However, in the presence of equimolar amounts of NaBAr\(^{′}\), the desired insertion into C–H bonds took place (Scheme 4). The use of copper- or gold-based catalysts induced different degrees of both chemo- and regioselectivities. Thus, only a 48% conversion (based on EDA) into the functionalized products was obtained with the Cu catalyst, whereas high (90%) conversions were observed in the Au case. The remaining EDA was converted into a mixture of diethyl fumarate and maleate. More interestingly, the regioselectivity of the reaction is completely reversed from copper to gold. The insertion into the tertiary C–H bond is clearly favored by 1 + NaBAr\(^{′}\), while the gold catalyst led to a very high selectivity (83%) toward the derivative formed from the insertion into the primary sites. To our knowledge, this is the highest value for the regioselectivity toward the primary sites obtained through carbene insertion from diazo compounds. Previous work from this laboratory with a silver-based catalyst gave 59% of the primary activation product,\(^{2\text{e}}\) and very recently Dias, Lovely, et al observed an 80% regioselectivity for this substrate with a different silver catalyst.\(^{2\text{f}}\) In the present system, it is also worth mentioning that the observation of a modest 12% product resulting from insertion into the primary sites with the copper complex 1 + NaBAr\(^{′}\) also constitutes the first example of the activation of such sites with copper. With the results presented herein, the three metals of group 11 have now been shown to induce such a transformation.

The relative regioselectivity obtained with Cu and Au illustrates a higher preference of the gold catalyst for primary over tertiary sites. The case of 2,3-dimethylbutane is very

As shown in Scheme 5, we employed catalytic amounts of the catalyst was generated by direct reaction of equimolar amounts of the complex IPrCuCl and one of the following salts: NaBAR', AgBF4, NH4PF6, and AgOTf, with the results shown in Table 1. It is clear that the use of different counterions has an effect on both the chemo- and regioselectivity. The PF6- containing precatalyst gave quantitative yields, whereas only 48% was obtained with the BAR' counterion. However, the latter provided a 10% regioselectivity toward the primary insertion, whereas the triflate and tetrafluoroborate precatalysts were completely selective toward the tertiary sites. To ascertain the nature of the species formed from the reaction of IPrCuCl and the salts shown in Table 1, we have independently performed the reaction of IPrCuCl and the halide scavengers on a synthetic scale. The reaction of equimolar amounts of I and the salts, at room temperature, in acetonitrile, has allowed the isolation of a series of complexes of general formula [IPrCu(NCMe)]X, for X = BAR', BF4, or PF6. In the case of the use of silver triflate, no coordinated acetonitrile has been detected, the spectroscopic data being consistent with the formulation IPrCuOTf. These four compounds have been characterized by NMR spectroscopy; their spectra are quite simple (see Experimental Section). Once characterized, these were tested as catalysts in the reaction of EDA and 2,3-dimethylbutane, in a series of experiments identical to those previously carried out with mixtures of IPrCuCl + MX. No significant differences between the two catalyst generation methods were observed, a fact that we interpret as evidence of the cationic moiety IPrCu+ as the active catalytic species. This is in good accord with previous work from this laboratory.8

**Effect of the NHC Ligand.** Once the influence of the metal and the anion of the halide scavenger in the catalytic reaction had been examined, we wondered whether the use of different NHC ligands, with a given metal—counterion pair, could affect the regioselectivity of this reaction. Studies of the electronic and steric effects of the NHC ligands have been recently performed.13 To gauge such effects in the present system, we conducted experiments with four complexes of general formula (NHC)AuCl14 (Scheme 3), again with 2,3-dimethylbutane as substrate. As shown in Table 2, there is a significant ligand effect both in the chemo- and in the regioselectivity of the reaction. In fact, there is a correlation between both selectivities: the higher the chemoselectivity, the higher the amount of products derived from the insertion into the primary sites. Since the electronic properties of these four NHC ligands have been proposed as very similar,13 it is reasonable to assume that the steric pressure around the catalytic pocket must be the main effect governing the regioselectivity.15 Such pressure should follow the order IPr > IAd > fBu > IMes. The unique reactivity

**Illustrative.** Tertiary and primary sites were activated, but the regioselectivity was reversed on going from Cu (12:88, primary:tertiary) to Au (83:17, primary:tertiary). Since the unique variation in both experiments (Scheme 4) is the metal center, it seems obvious that the explanation for such a different behavior must be focused on this specific feature. Initially, one could argue that the main difference between the copper and gold catalysts could be the volume of the catalytic pocket. However, we have collected data that play down the role of this factor. As shown in Scheme 5, we employed catalytic amounts of the complex IPrCuCl and one of the following salts: NaBAR', AgBF4, NH4PF6, and AgOTf, with the results shown in Table 1. It is clear that the use of different counterions has an effect on both the chemo- and regioselectivity. The PF6- containing precatalyst gave quantitative yields, whereas only 48% was obtained with the BAR' counterion. However, the latter provided a 10% regioselectivity toward the primary insertion, whereas the triflate and tetrafluoroborate precatalysts were completely selective toward the tertiary sites. To ascertain the nature of the species formed from the reaction of IPrCuCl and the salts shown in Table 1, we have independently performed the reaction of IPrCuCl and the halide scavengers on a synthetic scale. The reaction of equimolar amounts of I and the salts, at room temperature, in acetonitrile, has allowed the isolation of a series of complexes of general formula [IPrCu(NCMe)]X, for X = BAR', BF4, or PF6. In the case of the use of silver triflate, no coordinated acetonitrile has been detected, the spectroscopic data being consistent with the formulation IPrCuOTf. These four compounds have been characterized by NMR spectroscopy; their spectra are quite simple (see Experimental Section). Once characterized, these were tested as catalysts in the reaction of EDA and 2,3-dimethylbutane, in a series of experiments identical to those previously carried out with mixtures of IPrCuCl + MX. No significant differences between the two catalyst generation methods were observed, a fact that we interpret as evidence of the cationic moiety IPrCu+ as the active catalytic species. This is in good accord with previous work from this laboratory.8

**Effect of the NHC Ligand.** Once the influence of the metal and the anion of the halide scavenger in the catalytic reaction had been examined, we wondered whether the use of different NHC ligands, with a given metal—counterion pair, could affect the regioselectivity of this reaction. Studies of the electronic and steric effects of the NHC ligands have been recently performed.13 To gauge such effects in the present system, we conducted experiments with four complexes of general formula (NHC)AuCl14 (Scheme 3), again with 2,3-dimethylbutane as substrate. As shown in Table 2, there is a significant ligand effect both in the chemo- and in the regioselectivity of the reaction. In fact, there is a correlation between both selectivities: the higher the chemoselectivity, the higher the amount of products derived from the insertion into the primary sites. Since the electronic properties of these four NHC ligands have been proposed as very similar,13 it is reasonable to assume that the steric pressure around the catalytic pocket must be the main effect governing the regioselectivity.15 Such pressure should follow the order IPr > IAd > fBu > IMes. The unique reactivity

(15) Steric pressure around the reactive center is different than overall steric parameter, as it involves substituents and their specific spatial orientation.
profile displayed by IPr in terms of yield and selectivity is evident, and we are presently evaluating the chemo-regioselectivities of related ligands in this transformation.

**Expansion to Other Alkanes.** The results shown in the previous sections show that the highest conversions as well as the highest regioselectivities toward the primary sites have been achieved with a combination of the IPr ligand, the BAr′ salt (NaBAr′4) with a series of alkanes, linear and branched, in their reaction with ethyl diazoacetate. Table 3 displays the results observed in this study. A consistent trend for the entire series is observed: this catalytic system promoted the functionalization of primary C–H bonds in all substrates employed. As mentioned above, the activation of alkane C–H bonds by the method of carbene insertion has been described with few metals as catalyst. This number is even smaller for systems capable of performing the insertion into the primary C–H bonds: only rhodium-based and very recently silver-based catalytic systems are known to promote such functionalization. The direct comparison of the data shown in Table 3 with those reported with metal complexes prepared according to literature methods,8,9 even for our most complex systems is higher. Design of more selective systems is in progress.

In conclusion, we report on the catalytic behavior of (NHC)MCl complexes, in the presence of an halide scavenger, of the efficient insertion of the C=CH=O group (from ethyl diazoacetate) into C–H bonds of alkanes including primary C–H bonds. The regioselectivity is influenced by (i) the metal, (ii) the stereoelectronic properties of the ligand, and (iii) the counterion employed. The facile tunability of the present system is a key feature we are currently exploring in this and related catalytic transformations.

**Experimental Section.**

**General Procedures.** NMR spectra were run in a Varian Mercury 400 MHz spectrometer, using CDCl3 as the solvent. Mass spectra were carried out in a Varian Saturn 2100FT. GC analyses were recorded in a Varian CP-3800. Solvents were dried and degassed before use. All hydrocarbons, the halide scavengers, and the EDA were purchased from Aldrich and employed without any further purification. The (NHC)MCl complexes were prepared according to literature methods.

**Syntheses of the Complexes [IPrCu(NCMe)]X and [IPrCu-(OTf)].** Complex 1 was dissolved in acetonitrile, and 1 equiv of the salt (NaBAr′4, AgBF4, NH4PF6, or AgOTf) was added to the solution. After stirring for 5 min, the mixture was filtered off, and the filtrate was concentrated under vacuum until a precipitate appeared. In the case of NH4PF6 the reaction mixture was stirred overnight. Cooling at −20 °C overnight provided microcrystalline material of the complexes in 75%–85% yields. NMR spectra were recorded in CDCl3, showing the formation of the desired compounds.

**Selected NMR Data.** [IPrCu(CH3CN)]BF4. 1H NMR (400 MHz, CDCl3): δ 7.53 (t, J = 7.8 Hz, 2 H); 7.33 (d, J = 7.8 Hz, 4 H), 7.2 (s, 2 H), 2.49 (heptet, J = 6.8 Hz, 4 H), 2.1 (s, 3 H); 1.23 (m, 24 H), 1.35 (1H) NMR (100 MHz, CDCl3): 145.7, 134.2, 131.1, 124.6, 123.9, 29.0, 24.9, 24.2, 2.3, 13C(1H) NMR (100 MHz, CDCl3): 145.7, 134.2, 131.3, 124.6, 123.9, 28.9, 24.9, 24.1, 2.4. 31P NMR (CDCl3): 143.4 (heptet, J = 95 Hz). [IPrCu(CH3CN)]BAr′. 1H NMR (400 MHz, CDCl3): δ 7.68 (s, 8 H), 7.54–7.46 (overlapping, 6 H); 7.3 (d, J = 7.8 Hz, 4 H), 7.21 (s, 2 H), 2.43 (heptet, J = 6.8 Hz, 4 H), 1.91 (s, 3 H); 1.2 (d, J = 6.4 Hz, 12 H); 1.2 (d, J = 6.4 Hz, 12 H); 13C(1H) NMR (100 MHz, CDCl3): 162 (q, JF = 25 Hz), 145.7, 135.0, 131.3, 129.1 (q, 3JC-F = 34 Hz), 124.9 (q, 3JC-F = 271 Hz), 124.6, 124.3, 117.7, 28.9, 25.1, 3.8, 2.17. [IPrCu–OTf]. 1H NMR (400 MHz, CDCl3): δ 7.52 (t, J = 7.8 Hz, 2 H), 7.32 (d, J = 7.8 Hz, 4 H), 7.2 (s, 2 H), 2.5 (heptet, J = 6.8 Hz, 4 H), 1.2 (m, 24 H), 13C(1H) NMR (100 MHz, CDCl3): 145.6, 134.2, 131.1, 124.6, 123.9, 28.9, 24.8, 2.4.

**Catalytic Experiments.** The catalysts were generated in situ (or some cases previously isolated as in the previous paragraph) in the following manner: the complex 1 or 2 (0.025 mmol) was dissolved in a mixture of 5 mL of CH2Cl2 and 5 mL of the substrate, and 1 equiv of the halide scavenger was added to the solution. After 15 min of stirring, 0.5 mmol of EDA was added from a syringe pump (dissolved in CH2Cl2) for 12 h. After 1 h of additional stirring, the mixture was analyzed by GC and GC-MS. The volatiles were
